(Received 21 September 2018; accepted 13 November 2018; published online 5 December 2018)

Discrete time quantum walks are unitary maps defined on the Hilbert space of coupled two-level systems. We study the dynamics of excitations in a nonlinear discrete time quantum walk, whose fine-tuned linear counterpart has a flat band structure. The linear counterpart is, therefore, lacking transport, with exact solutions being compactly localized. A solitary entity of the nonlinear walk moving at velocity v would, therefore, not suffer from resonances with small amplitude plane waves with identical phase velocity, due to the absence of the latter. That solitary excitation would also have to be localized stronger than exponential, due to the absence of a linear dispersion. We report on the existence of a set of stationary and moving breathers with almost compact superexponential spatial tails. At the limit of the largest velocity $v = 1$, the moving breather turns into a completely compact bullet. *Published by AIP Publishing.* <https://doi.org/10.1063/1.5060654>

In this work, we utilize a nonlinear generalization of a discrete time quantum walk (DTQW), which is widely used in the field of quantum computing including experimental realizations. This unitary map toolbox allows one to study numerically the dynamics of solitary type excitations in discrete lattices with great efficiency. The linear DTQW is fine-tuned to a dispersion relation with two flat bands which inhibit transport and allow for compact localized states. Nonlinearity leads to the appearance of stable moving and stationary nonlinear excitations which are superexponentially localized. The system further allows for fully compact bullet excitations moving with the maximum velocity, which may also form an intriguing interacting gas with unusual scattering properties.

I. INTRODUCTION

Discrete breathers (DBs)^{1,2} are generic time-periodic and spatially localized solutions to broad classes of nonlinear Hamiltonian network equations.³ Discrete breathers have been observed and studied in a fascinating and broad setting of physical realizations which cover several decades of temporal and spatial scales (see Ref. 2 for a detailed review). If the band structure of the linear part of the Hamiltonian network is not degenerate, then DBs are localized in space either following an exponential decay (for analytical band structure functions) or an algebraic one (for non-analytical ones).⁴ If the band structure is degenerate and consists of flat band(s) only, DBs localize superexponentially fast.⁵ For specific local symmetries of flat bands, DBs can even maintain the compactness of the corresponding compact localized eigenstates of the linear Hamiltonian network equations.⁶

The generic appearance of DBs in lattice structures comes at a price. The absence of a continuous translational invariance (which is replaced at best by some discrete one)

makes travel hard. Attempts to obtain moving DBs through the excitation of antisymmetric perturbations of stationary DBs lead to the proposal of various numerical procedures.^{7,8} These methods typically result in excitations which radiate during propagation and eventually stop moving. Indeed, multiple attempts to obtain lossless traveling discrete breathers suffered from facing resonances between the velocity v of a moving DB candidate and phase velocities of small amplitude plane waves.² These—usually unavoidable—resonances produce nondecaying tails. Relief could only be obtained by choosing generalized discrete nonlinear Schrödinger equations. Their global phase (or simply gauge) symmetry allows finding stationary DBs supported by just one harmonics in time. Then tailless moving DBs could be obtained for a discrete and non-empty set of velocity values v .^{9,10} In contrast, systems with continuous translational invariance not only allow for Galilean or Lorentz boosting of solitary excitations if their stationary parents exist but also permit the occurrence of completely compact moving solitary excitations in nonlinear partial differential equations which have a missing linear dispersive part.¹¹ Interestingly, James reported recently on an attempt to find traveling DBs in a strongly nonlinear discrete nonlinear Schrödinger chain with a missing linear dispersive part.¹² However, even in this case, nondecaying tails were observed.

In this work, we consider nonlinear generalizations of discrete time quantum walks (DTQW) as a promising way to overcome the above difficulties of Hamiltonian networks. DTQW were introduced as quantum generalizations of classical random walks by Aharonov *et al.*¹³ The DTQW evolution is given by a (discrete) sequence of unitary operators acting on a quantum state of a chain of two-level systems in a high-dimensional Hilbert space.^{14–16} DTQW exhibit quantum interference and superposition,¹³ entanglement,¹⁷ two-body coupling of wave functions,¹⁸ and Anderson localization.^{16,19}

DTQW experimental realizations were reported with ion trap systems,²⁰ quantum optical waveguides,²¹ and nuclear magnetic resonance quantum computing.²² DTQW maps can be considered as generated by Floquet driven quantum Hamiltonians, without precise knowledge of the Hamiltonian. Through a fine-tuning of the DTQW control parameters, it is straightforward to inhibit transport by making the complete band structure flat.¹⁶ Moreover, it is straightforward to include nonlinear terms while keeping the unitarity of a generalized nonlinear DTQW.²³ It is worthwhile to note that linear and nonlinear unitary DTQW are a particular case of in general nonunitary coupled map lattices,^{24,25} which are widely used to study the dynamics of populations, chemical reactions, fluid flow, and biological networks.

By making use of direct numerical simulations and complimentary generalized Newton schemes, we arrive at a plethora of nonlinear DTQW breathers. The breathers lose compactness for arbitrary weak nonlinearity and develop superexponential tails. They can be stationary, but also moving with a dense set of velocities. Analytical results fit well with numerical observations. The paper is organized as follows: In Sec. II, we introduce the nonlinear DTQW. In Sec. III, we study the resulting dynamics. Section IV provides with conclusions.

II. THE NONLINEAR DISCRETE TIME QUANTUM WALK

The dynamics of the nonlinear DTQW is evolving a two-component wave function $\hat{\psi}_n(t) = \{\psi_{+,n}(t), \psi_{-,n}(t)\}$ in space and time. The nonlinear DTQW dynamics is controlled by coin operators \hat{U}_n which are unitary matrices in general determined by four site dependent angles.¹⁶ For our purposes, we choose the simplest and generic version controlled by only one angle type

$$\hat{U}_n = \begin{pmatrix} \cos \theta_n & \sin \theta_n \\ -\sin \theta_n & \cos \theta_n \end{pmatrix}, \quad (1)$$

where the angles $\theta_n = \theta + \lambda S_n$ are nonlinear functions of $\hat{\psi}_n$ with the norm density per site $S_n = (|\psi_{+,n}|^2 + |\psi_{-,n}|^2)$. Including the shift operator (see Ref. 16 for details), we arrive at the nonlinear unitary map of the whole chain of two-level systems (see also the schematic DTQW evolution in Fig. 1)

$$\psi_{\pm,n}(t+1) = \cos \theta_{n\mp 1} \psi_{\pm,(n\mp 1)}(t) \pm \sin \theta_{n\mp 1} \psi_{\mp,(n\mp 1)}(t). \quad (2)$$

Note that for finite systems with N sites, periodic boundary conditions are to be applied. The above evolution is unitary and preserves the total norm of the wave function $S = \sum_{n=1}^N S_n$. Moreover, the model enjoys stroboscopic sublattice factorization (SSF), i.e., the evolution on even and odd sites decouples locally if iterated over two time units. Indeed, it follows from Eq. (2) that $\hat{\psi}_n(t+2) =$

FIG. 1. A schematic representation of a general discrete-time quantum walk. The vertical arrows indicate the quantum coin action within each two-level system, while the horizontal ones show the action of the transfer operator.

$F[\hat{\psi}_{n-2}(t), \hat{\psi}_n(t), \hat{\psi}_{n+2}(t)]$. For even N , it follows that the dynamics on even and odd sites decouples completely, similar to the two distinct sides of a Möbius band with zero twists. Instead, for odd N , the even and odd site dynamics is globally coupled: any excitation on an even site will explore all even sites until it reaches the boundary where it turns odd and vice versa. This is similar to a Möbius band with a nontrivial twist.

In the linear regime $\lambda = 0$, the coin operators turn identical and space-index independent. That allows one to seek solutions in the form of plane waves $\hat{\psi}_n(t) = \hat{\psi} \exp[i(\omega t + kn)]$. The corresponding dispersion relation reads¹⁶

$$\cos(\omega) = \cos(\theta) \cos(k). \quad (3)$$

We note that for the particular choice $\theta = \pi/2$, the resulting band structure is composed of two flat bands $\omega = \pm\pi/2$. In this case, compact localized eigenstates exist,¹⁶ and the quantum walk dynamics is quenched resulting in the halt of any propagating wave. Adding back the nonlinear terms with $\lambda \neq 0$, any possible observed transport will be entirely due to the nonlinear terms which lead to an interaction between the compact localized states. For the remaining part of this work, we will use $\theta = \pi/2$ only.

III. DISCRETE BREATHERS

A. Numerical observations

We study the evolution of a single-site initial condition $\hat{\psi}_n(0) = \frac{\delta_{n,n_0}}{\sqrt{2}} \{1, 1\}$ with the wave function norm $S = 1$, launched at site n_0 . We use a system with size $N = 2000$ and periodic boundary conditions and evolve up to time $t = 10^4$. The resulting evolution of the norm density distribution is shown in Fig. 2 for $\lambda = 0.1$. A part of the excitation remains in a relatively narrow core region which spreads, albeit very slowly. Our main observation is that the core emits solitary type excitations at various times, which then continue to travel separately at various velocities. These objects are obvious candidates for traveling discrete breathers. In the following, we will analyze them in detail.

FIG. 2. Typical temporal and spatial pattern of the nonlinear DTQW dynamics. Norm density S_n is plotted versus time and space with color coding on a logarithmic scale. $\lambda = 0.1$, with initial condition $\hat{\psi}_n(0) = \frac{\delta_{n,n_0}}{\sqrt{2}} \{1, 1\}$ and $n_0 = 1000$. The arrow indicates the moving solitary excitation analyzed in greater detail in Fig. 3.

B. Cut and paste

Since the moving solitary type excitations are well separated in space, we apply a ‘‘Cut and Paste’’ procedure. We (i) evolve the system up to an appropriate cutting time t_c , (ii) identify the position n_c of the core of a single isolated object, (iii) obtain the distance l_c from the core at which the wave function amplitudes decay to noise levels $\sim 10^{-3}$, and (iv) zero the wave function amplitudes for all sites $n < n_c - l_c$ and $n > n_c + l_c$. With a trivial re-shifting of time and space coordinates, we continue the evolution of the single moving object and its analysis. In particular, we repeat the ‘‘Cut and Paste’’ procedure several times, in order to allow the excitation to converge to a state which is almost radiationless, i.e., which is not leaving weakly excited sites behind. In order to get a real-valued object, we take an absolute value of each component of $\hat{\psi}$ and repeat the procedure.

An example is shown in Fig. 3. It corresponds to an originally found moving solitary object with approximate speed $v \approx 1/37$ indicated by the arrow in Fig. 2. The profile of the norm density distribution $S_n(t_c)$ is shown in Fig. 3(a). It is almost compactly localized. To zoom into the tails, we plot $\log_{10} S_n(t_c)$ in the inset of Fig. 3(a) and observe tails which are decaying faster than exponential, i.e., superexponential (see more details below). Due to the small velocity of that solitary excitation, it is much more instructive to observe the evolution by following the time dependence of the wave function amplitude at a given site. Using the SSF symmetry, we will monitor the evolution of ψ_n for a few particular even sites at even times. The time-dependence of $|\psi_{\pm n}|^2$ for the right-moving excitation from Fig. 3(a) is shown in Fig. 3(b) for six consecutive even sites $n = 40, 42, 44, 46, 48, 50$ and for even times $t = 2t_e$. We observe equidistantly shifted curves for each of the wave function components which indicate a motion at constant speed v , and a symmetry between the evolution of both wave function components:

$$\psi_{\pm n+2} \left(t + \frac{2}{v} \right) = \psi_{\pm n}(t), \quad \psi_{+n} \left(t + \frac{1}{v} \right) = -\psi_{-n}(t). \quad (4)$$

Together with faster than exponential tail decay it follows that the rear tail profile of that right moving solitary excitation satisfies the inequalities

$$|\psi_{+,n}(t)| \ll |\psi_{-,n}(t)| \ll |\psi_{+,n+2}(t)|. \quad (5)$$

Note that it is straightforward to generalize these inequalities to the front tail of a right moving solitary excitation and to left moving excitations as well. We will use these conditions below to obtain analytical results. Finally, we plot the time dependence of the norm $S_{40}(t_e)$ in Fig. 3(c) on a double logarithmic scale. The superexponential decay of both the front and the rear tails are clearly observed.

C. Tail analysis

In order to describe the tails of a moving solitary excitation, we expand Eq. (2) to first order in $\lambda S_n \ll 1$:

$$\psi_{\pm n}(t+1) = -\lambda S_{n\mp 1}(t) \psi_{\pm n\mp 1}(t) \pm \psi_{\mp n\mp 1}(t). \quad (6)$$

Reducing the analysis to even times and sites (SSF symmetry) and accounting for the inequalities (5) in the rear tail, we

FIG. 3. Analysis of a moving solitary excitation with total norm $S = 0.175$ and $\lambda = 0.1$. (a) Snapshot of the norm density distribution $S_n(t)$ versus n . (b) The time evolution of $|\psi_{\pm n}|^2$ for $n = 40, 42, 44, 46, 48, 50$ (from left to right). Solid lines, $|\psi_{+,n}|^2$; dashed lines, $|\psi_{-,n}|^2$. The vertical black line guides the eye for the observation of a symmetry between both (see text for details). (c) S_{40} versus even time t_e on double logarithmic scale (blue solid line). Red dashed lines show the predicted superexponential decay [see Eqs. (12) and (13)].

arrive at

$$\begin{aligned} \psi_{+,2n}(2t) + \psi_{+,2n}(2t-2) &= -\lambda G[\psi_{-,2n}(2t-2)], \\ \psi_{-,2n}(2t) + \psi_{-,2n}(2t-2) &= \lambda G[\psi_{+,2n+2}(2t-2)], \end{aligned} \quad (7)$$

where $G[\psi] = |\psi|^2 \psi$. To solve the above equations, we use the traveling wave ansatz

$$\begin{aligned} \psi_{+,2n}(2t) &= (-1)^{t+n} g_r(2vt - 2n), \\ \psi_{-,2n}(2t) &= (-1)^{t+n+1} g_r(2vt - 2n - m), \end{aligned} \quad (8)$$

with a yet to be determined argument shift m . The real-valued rear tail function $g_r(x)$ satisfies the difference equations

$$\begin{aligned} g_r(y) - g_r(y-2v) &= -\lambda g_r^3(y-m), \\ g_r(y-m) - g_r(y-2v-m) &= -\lambda g_r^3(y-2), \end{aligned} \quad (9)$$

with $y = 2vt - 2n$. Since both equations have to deliver the same solution, we conclude that $m = 1$, confirming the validity of Eq. (4).

If the velocity of the moving solitary excitation with core position $y = n_c$ is small, i.e., $v \ll 1$, we can replace the difference equations (9) by a nonlinear differential equation with a discrete delay to describe the rear tail dynamics:

$$2vg'_r(y) = -\lambda g_r^3(y-1), \quad y \ll n_c. \quad (10)$$

A straightforward generalization to the front tail dynamics yields

$$2vg'_f(y) = \lambda g_f^3(y+1), \quad y \gg n_c. \quad (11)$$

Both rear and front tail differential equations (10) and (11) yield the super-exponential decay solution

$$g(y) = A \exp[-\alpha e^{|y|/\xi} + \beta|y|], \quad |y - n_c| \gg 1. \quad (12)$$

Indeed, by substituting (12) into (10) and (11), we obtain the super-exponential decay length ξ :

$$\xi = 1/\ln 3, \quad \beta = 1/(2\xi), \quad 2v\alpha/\xi = \lambda e^{-3\beta A^2}. \quad (13)$$

The super-exponential decay is plotted in Fig. 3(c) and agrees very well with the numerically observed front and rear tails.

Both tail solutions have to be glued together in the core of the moving excitation, where the above analysis does not hold. Therefore, in general, A could be different in front and tail for asymmetric profiles. However, the numerical results in Figs. 3(b) and 3(c) clearly indicate that the profiles are symmetric. Together with the reasonable assumption that the square amplitude in the tails is proportional to the total norm S of the whole moving solitary excitation $|A|^2 \propto S$, we arrive at the scaling relation

$$v \propto \lambda S. \quad (14)$$

To test this scaling relation, we perform a single “cut and paste” procedure to a number of moving solitary excitations as shown, e.g., in Fig. 2, measure their norm and velocity, and plot the result in Fig. 4. We observe good agreement with (14) for $\lambda S \leq 0.7$ and corresponding velocities $v \leq 0.4$.

FIG. 4. The dependence of the discrete breather velocity v on the parameter λS . Green triangles: Newton-generated periodic solutions; red circles: quasi-periodic solutions; blue squares: transient chaotic solutions. Black diamond: analytical bullet solution. The insets show the corresponding generalized Poincaré sections.

D. Moving discrete breathers

For the range of parameters $\lambda S < 0.9$, we were able to obtain a number of moving discrete breathers by applying the procedure of “cut and paste” once. We characterize the internal dynamics of these objects by computing a generalized Poincaré section in a comoving frame. At each time t , we obtain the position m of the largest value of $S_n(t)$ and plot S_{m+2} versus S_m . The results are shown in Fig. 5. We find three different types of discrete breathers: periodic, quasiperiodic, and chaotic.

Periodic moving discrete breathers are characterized by a rational value of their velocity which leads to a finite number of points on the Poincaré section as shown in Fig. 5(a), where $v = 1/37$, $\lambda = 0.1$, and $S = 1$. The profile of the moving discrete breather is fully restored after 37 iterations and one additional shift along the lattice (up to a global phase).

FIG. 5. The Poincaré sectioning of moving discrete breathers (see text for details). (a) Periodic discrete breather with rational velocity $v = 1/37$, $\lambda = 0.1$, and $S = 1$. The arrows show the iteration order. (b) Quasiperiodic discrete breather with velocity $v \approx 0.041$, $\lambda = 0.5$, and $S = 0.15$. (c) Chaotic discrete breather with $v \approx 0.39$, $\lambda = 1.7$, and $S = 0.42$.

Quasiperiodic moving discrete breathers have an irrational velocity with a Poincaré section which forms a dense one-dimensional line segment for an infinite number of iterations. An example is shown in Fig. 5(b) for $v \approx 0.041$, $\lambda = 0.5$, and $S = 0.15$.

Chaotic moving discrete breathers generate a Poincaré section which corresponds to a stripe segment with finite width and additional fine (potentially fractal) structure inside. An example is shown in Fig. 5(c) for $v \approx 0.39$, $\lambda = 1.7$, and $S = 0.42$. Chaotic moving discrete breathers cannot be cast into the form of a traveling wave solution (8), and therefore, cease to be exact solutions. Instead, these objects are slowly losing the norm by radiating plane waves in their wake. These leftovers do not propagate further due to the flat band structure of the small amplitude equations. Thus, the chaotic moving breathers are slowing down their speed v . The rate of that process is probably related to the thickness of the above stripe segments in the Poincaré sections. Still, that rate can be very small such that we observe traveling chaotic breathers over several thousands of lattice sites without a notable change of their speed.

Quasiperiodic moving discrete breathers instead can very well correspond to exact traveling wave solutions. However, it may well be that these objects are chaotic breathers with very narrow and thus undetected finite width of the stripe segments. It may also well be that these objects are in fact exact traveling waves but with rational values of their velocity v which lead to a period which is of the order of the simulation time. We are not aware of fine computational means to tell these different scenarios apart.

Periodic moving discrete breathers can be obtained with very high numerical precision using a generalized Newton scheme. For that we compactly rewrite Eq. (2) as a unitary map of the entire field $\hat{\Psi} \equiv \{\hat{\psi}_n\}$. The action of one iteration in (2) is just a nonlinear unitary map $\hat{\Psi}(t+1) = \mathcal{U}\hat{\Psi}(t)$. A translation shift along the lattice by one lattice site will be denoted by $\mathcal{T}\{\hat{\psi}_n\} = \{\hat{\psi}_{n+1}\}$. Then, a periodic moving breather is encoded by two integers p, q and its frequency Ω such that the breather field satisfies

$$(\mathcal{U}^q - e^{i\Omega q} \mathcal{T}^p) \hat{\Psi} = 0, \quad v = \frac{p}{q}. \quad (15)$$

FIG. 6. Snapshots of spatial distributions of $|\psi_{\pm}|^2$ for two periodic moving discrete breathers are shown. Solid lines, $|\psi_{+n}|^2$; dashed lines, $|\psi_{-n}|^2$. These periodic solitary excitations correspond to values of $p = 1, q = 37$ (blue lines) and $p = 1, q = 3$ (orange lines).

Solutions to (15) can be obtained using standard Newton schemes which search for zeros of vector functions.²⁶ We found two such solutions. The first one was described above and has velocity $v = 1/37$, $q = 37, p = 1$, and $\Omega = \pi/37$. The second one has velocity $v = 1/3$, $q = 3, p = 1$, and $\Omega = 2\pi/3$. Both solutions are shown with green circles in Fig. 4. The profiles of both solutions are shown in Fig. 6.

E. Bullets

For the particular value of the nonlinearity $\lambda S = \pm\pi/2$, Eq. (2) admit exact moving and compact excitations, which we coin *bullets*. These bullets have a nonzero field amplitude on only one lattice site and in addition on only one of the two wave function components. Its velocity $v = \pm 1$ (see Fig. 4). A right-moving bullet is given by

$$\hat{\psi}_n(t) = (-1)^{st} \sqrt{S} \{e^{i\phi_+}, 0\} \delta_{n, n_0+t}, \quad (16)$$

with $s = \pm 1$ being the sign of λ . A left-moving bullet is given by

$$\hat{\psi}_n(t) = (-1)^{st} \sqrt{S} \{0, e^{i\phi_-}\} \delta_{n, n_0-t}. \quad (17)$$

Thus, the dynamics of a single bullet is characterized by two

FIG. 7. Evolution of a bullet gas with randomly chosen initial coordinates and phases. (a) Spatial and temporal dependence of the norm density, $S_n(t)$; (b) Bullet phases (modulo of 2π), ϕ_{\pm} , as the function of space and time; (c) Time evolution of the smallest S_{min} .

conserved quantities—the total norm $S = \pi/(2|\lambda|)$ and the phase ϕ_{\pm} . Interestingly, the dynamics of a gas of left and right moving bullets shows the conservation of the numbers of left and right movers. Two bullets approaching each other will experience no interaction if their relative distance is odd, but will undergo an act of elastic scattering if that distance is even. After such an elastic reflection, a left mover is turned into a right mover (carrying its phase ϕ with it) and vice versa. The evolution of such a gas of left and right moving bullets is shown in Figs. 7(a) and 7(b). The dynamics of the gas will lead to instabilities in the presence of a small noisy background. This background is generated during the computation due to roundoff errors. It is observed in Fig. 7(a) at times $t \approx 500$. The time dependence of the smallest background norm S_{min} during that evolution is shown in Fig. 7(c). The background intensity is growing exponentially fast up to times $t \approx 1400$. Yet, for larger times, the system still shows up with an interacting gas of moving solitary excitations with various velocities [see Fig. 7(a)].

FIG. 8. (a) A snapshot of a single frequency stationary breather solution. Solid line, $|\psi_{+,n}|^2$; dashed line, $|\psi_{-,n}|^2$; (b) spatial dependence of S_n showing super-exponential decay in its tails [the red dashed line corresponds to the solution of (20)]; (c) scaling of the breather frequency with the parameter λS .

F. Stationary discrete breathers

In addition to the above surfeit of moving discrete breathers, we also report on the existence of stationary discrete breathers with zero velocity. These objects are zeros of the nonlinear map

$$(\mathcal{U}^q - e^{i\Omega q} \mathcal{I}) \hat{\Psi} = 0, \quad (18)$$

where \mathcal{I} is the unity operator. Below, we will consider the case $q = 1$ only. Solutions can be again searched for by using a generalized Newton scheme. The spatial profile of one of these solutions is shown in Fig. 8(a). A double logarithmic plot of the profile in Fig. 8(b) reveals its superexponential tails. Interestingly, the deviation of the stationary breather frequency Ω from $\pi/2$ yields a linear dependence on the control parameter λS [see Fig. 8(c)].

To obtain an analytical solution for the tails of a stationary breather, we use the observation from Fig. 8(a) that one of the two components is dominating in the tail, e.g., $|\psi_{+,n}| \gg |\psi_{-,n}|$ for the right tail of the breather. Note that the final result will be invariant on the choice of the tail. With the ansatz

$$\begin{aligned} \psi_{+,n}(t) &= \exp[i\Omega t + \phi_+] g(n), \\ \psi_{-,n}(t) &= \exp[i\Omega t + \phi_-] g(n + n_0), \end{aligned} \quad (19)$$

and Eq. (6), we obtain $n_0 = 1$ and

$$2g(n) \cos \Omega = -\lambda g^3(n-1). \quad (20)$$

The solution of the above nonlinear difference equation yields the super-exponential decay $g(n) = A \exp[-\alpha e^{|n|/\xi}]$, $|n| \gg 1$ with $\xi = 1/\ln 3$. The frequency of the breather is determined by both the nonlinearity and its norm: $(\Omega - \pi/2) \propto \lambda S$, and this scaling is in a good accord with numerical analysis [see Fig. 8(c)].

IV. CONCLUSIONS

Discrete time quantum walks are unitary maps defined on the Hilbert space of coupled two-level systems, which turn into a very efficient unitary toolbox for addressing a variety of problems which lack easy solutions in Hamiltonian settings. In particular, we studied the dynamics of excitations in a nonlinear discrete time quantum walk, whose fine-tuned linear counterpart has a flat band structure. The linear counterpart is, therefore, lacking transport, with exact solutions being compactly localized. A solitary entity of the nonlinear walk moving at velocity v is then shown to not suffer from resonances with small amplitude plane waves with identical phase velocity, due to the absence of the latter. That solitary excitation also shows to be localized stronger than exponential, due to the absence of a linear dispersion. We found a set of stationary and moving breathers with almost compact superexponential spatial tails. At the limit of the largest velocity $v = 1$, the moving breather turns into a completely compact bullet. Remarkably, these bullets can form an interacting gas with the bullet phases participating in the scattering process. It remains an interesting question as to whether such highly localized—and even compact—moving nonlinear solitary excitations may be used in applications involving discrete time quantum walks.
