The microcanonical Gross-Pitaevskii (also known as the semiclassical Bose-Hubbard) lattice model dynamics is characterized by a pair of energy and norm densities. The grand canonical Gibbs distribution fails to describe a part of the density space, due to the boundedness of its kinetic energy spectrum. We define Poincaré equilibrium manifolds and compute the statistics of microcanonical excursion times off them. The tails of the distribution functions quantify the proximity of the many-body dynamics to a weakly nonergodic phase, which occurs when the average excursion time is infinite. We find that a crossover to weakly nonergodic dynamics takes place inside the non-Gibbs phase, being unnoticed by the largest Lyapunov exponent. In the ergodic part of the non-Gibbs phase, the Gibbs distribution should be replaced by an unknown modified one. We relate our findings to the corresponding integrable limit, close to which the actions are interacting through a short range coupling network.

Equi-partition and thermalization are cornerstone concepts of understanding stability and predictability of complex matter dynamics. Proximity to integrable limits may have a strong impact on the needed time scales, or even on equi-partition itself. Let us consider a dynamical system which is characterized by a countable set of preserved actions at the very integrable limit, as, e.g., for harmonic lattice vibrations in crystals. Close to the limit, nonintegrable couplings between the actions induce a nontrivial dynamics of the latter. The nonintegrable couplings define a certain connectivity network on the action lattice.

The nonlinear coupling network of the actions can be long ranged. That is precisely the case with translationally invariant weakly nonlinear lattice wave equations, or phonon dynamics in crystals, or, e.g., the celebrated Fermi-Pasta-Ulam (FPU) chain [1,2]. Then the linear integrable limit yields actions which are related to standing or plane waves (harmonic phonons) that traverse the entire system. Weak local nonlinearities therefore induce a coupling network which is long ranged [2]. At whatever small, but finite, energy densities in an equi-partitioned state, all plane waves and thus actions will be coupled regardless of their characteristics (e.g., the eigenfrequency). Selection rules due to momentum conservation do not alter the above argument. Nature nicely confirms that, since phonon dynamics in crystals appears to be equi-partitioned down to the smallest temperatures. At the same time, approaching zero densities will lead to a diminishing of the largest Lyapunov exponent, and thus equi-partition times are expected to smoothly diverge in the very limit.

The focus of this work is the case of a Gross-Pitaevskii (GP), also known as Bose-Hubbard (BH), lattice with local nonlinear many-body interactions, and short range hoppings.

In the limit of large densities the nonlinear interactions dominate over the hoppings, the actions turn local in real space, and the system disintegrates into an uncoupled set of strongly anharmonic oscillators in real space. Close to the limit the short range hoppings induce a nonintegrable short range coupling network between the actions. Anomalous and potentially nonergodic large density dynamics was reported for the GP lattice [3–6], including nonequilibrium transport properties [7,8] and self-localization [9–11]. Indications for nonergodic dynamics were also observed for similar model classes [12,13].

Strict nonergodic dynamics implies a separation of the phase space into disjoint parts under the action of Hamiltonian dynamics, which could imply the presence of additional symmetries. Such symmetries are unlikely to be restored upon the smooth change of control parameters. An alternative scenario is observed in glassy dynamics, as, e.g., shown by Bouchaud via the appearance of consecutive metastable states, whose lifetimes are distributed according to power-law distributions [14]. If the average lifetime of the metastable states turns infinite, a trajectory might still visit almost all the phase space; however, strictly an infinitely long time is required to observe that when computing averages. Such dynamics, while formally being ergodic, turns nonergodic for any finite averaging time. Similar behavior has been discussed by Bel, Rebenshtok, and Barkai in a set of papers dedicated to continuous-time random walks [15–17]. Therein, the phenomenon goes under the name of weak ergodicity breaking, or weak nonergodicity. Lutz further formalized the connection between power-law distribution and weak nonergodicity in the context of optical lattices [18].

The goal of this work is to show the existence of a weak nonergodic phase of the GP lattice dynamics and to...
quantitatively assess the crossover line from an ergodic to a weak nonergodic regime in the relevant two-dimensional density parameter space. The GP lattice dynamics is conserving energy and norm (particle number). The microcanonical dynamics is depending on the corresponding pair of densities. If the dynamics is ergodic, the time average of an observable (a function of the phase space coordinates) should exist and be equal to a phase space average with a proper distribution function. Assuming equal weight of microstates, the Boltzmann (canonical) or Gibbs (grand canonical) distributions are the proper choice. Rasmussen et al. showed that the Gibbs distribution with positive temperature and arbitrary chemical potential is addressing only a part of the accessible microcanonical density space \(^3\). Negative temperatures yield divergent partition functions, and a proper non-Gibbs distribution for the complementary space is not known. In that non-Gibbs density space the microcanonical dynamics is characterized by anomalous fluctuations, slow relaxations, and potentially (weakly) nonergodic dynamics. We note that the mere fact of a non-Gibbs regime is not sufficient to conclude that the dynamics is nonergodic, since the analysis is based solely on phase space integrations and does not consider any aspect of the accompanying dynamics.

Our strategy is to use proper observables \(f\) as functions of the phase space variables. Assuming ergodicity we may obtain the expected phase space average \(\bar{f}\). The condition \(f = \bar{f}\) defines an equilibrium Poincaré manifold of codimension 1 which separates the accessible microcanonical phase space into two disjoint sets. By assumption of ergodicity, a microcanonical trajectory must pierce this manifold infinitely many times during its evolution, to ensure that the microcanonical time average \(\langle f \rangle = \bar{f}\). Let us consider the event of two consecutive piercings, and the trajectory excursion off the manifold in between. We will assess the statistics, correlations, and other properties of these excursions. At variance with correlation function computations, our strategy allows us to return to individual excursions which contribute to a particular feature. In a recent study [19] of a finite FPU system, an entropy function on the system phase space was used as an observable \(f\). This integral quantity becomes insensitive to relevant nonergodic fluctuations in the limit of large volume \(N\). The key ingredient in this work is to use simultaneously all observables which correspond to integrals of motion in the large density limit. The piercings of one single trajectory through \(N\) equilibrium manifolds will then be analyzed.

The one-dimensional GP lattice equations read

\[
i\frac{\partial \psi_m}{\partial t} + (\psi_{m+1} + \psi_{m-1}) - g|\psi_m|^2\psi_m = 0, \tag{1}
\]

where \(m\) labels the lattice sites, and \(g\) is a nonlinear parameter related to the two-body scattering length.

Equation (1) is generated by the Hamiltonian equations of motion \(i\psi_m = \partial H/\partial \psi^*_m\) with the Hamiltonian

\[
H = \sum_m \left[ -(\psi_m^*\psi_{m+1} + \psi_m\psi_{m+1}^*) + \frac{g}{2}|\psi_m|^4 \right]. \tag{2}
\]

Here, \(\psi_m^*\) and \(\psi_m\) are pairs of conjugated phase space variables, the sum runs over \(N\) lattice sites, and periodic boundary conditions \(\psi_1 = \psi_{N+1}\) are used. In addition to the total energy \(H\), the above equations also conserve the norm \(A = \sum_m |\psi_m|^2\) which is the classical analogue to the quantum mechanical total number of particles. The canonical transformation \(\psi_m = \sqrt{A_m} \exp(i\phi_m)\) maps Eq. (2) into

\[
H = \sum_m \left[ -2\sqrt{A_m}A_{m+1}\cos(\phi_m - \phi_{m+1}) + \frac{g}{2}|A_m|^2 \right]. \tag{3}
\]

Rasmussen et al. [3] used Eq. (3) to compute the classical grand-canonical partition function

\[
Z = \int_0^\infty \int_0^{2\pi} \prod_{m=1}^N d\phi_m dA_m e^{-\beta[H + \mu A]} . \tag{4}
\]

Here \(\mu\) is the chemical potential and \(\beta\) the inverse temperature \(\beta = 1/T \geq 0\). The mapping of the pair of Gibbs parameters \(\{\beta, \mu\}\) onto the microcanonical density space \(\{h, a\}\) with \(h = H/N\) and \(a = A/N\) leaves a part of the high energy density space unaddressed, with the infinite temperature \(\beta = 0\), \(\beta A = 0\), being the border between the addressable density space part (Gibbs regime) and the complementary one (non-Gibbs regime) [3]. It is convenient to use rescaled densities \(x = ga, y = gh\). Then the Gibbs part of the density space is sandwiched between the zero temperature \(\beta = \infty\) line \(y_{GS} = -2x + x^2/2\) and the infinite temperature \(\beta = 0\) one \(y_{NG} = x^2/\beta\) in Fig. 1. It was conjectured that microcanonical dynamics in the non-Gibbs phase is nonergodic due to the observed formation of concentrated hot spots of localized norm or energy excitations [3]. These excitations appear to be related to exact discrete breather solutions [20–23]. Interestingly, these exact finite energy time-periodic solutions are continuables into single site anharmonic oscillator excitations in the integrable limit of infinite densities, coined the anticontinuous limit by MacKay and Aubry [24]. Rumpf developed an entropic picture of fragmentation of the field into two components in the non-Gibbs regime—a condensate of the above hot spots, and a remaining thermalized component with infinite temperature \(\beta = 0\) [4,5]. Whether the spots thermalize and whether the system is ergodic or not, remained unaddressed. This leads to the question, whether the GP lattice turns nonergodic precisely in the non-Gibbs regime. Below we will study lifetime distributions of the hot spots, show that these times stay finite inside a part of the non-Gibbs regime, and discuss the consequences. We also note that homogeneous norm...
density distributions. For energy densities non-Gibbs dynamics can be generated with initial states located in the non-Gibbs regime for integrate a trajectory and track the times times follow as which tell us whether we monitor an excursion with local augmentation (+) or depletion (−) of the norm density. We then obtain the probability distribution functions (PDF) of the excursion times \( \tau \). We attempt to fit the PDF tails with a power law \( P(\tau) \propto \tau^{-\alpha} \) to find the dependence of \( \alpha \) on the densities \((x, y)\). For \( \alpha \leq 2 \) we conclude that the dynamics is weakly nonergodic, since the average of the excursion times \( \tau \) diverges.

We note that we can not exclude the presence of exponential cutoffs in the unresolvable part of \( P \) at large values of \( \tau \). We checked that the precise form of the chosen initial states is not relevant in the ergodic regime. All that matters are the values of \( x \) and \( y \). We further compute the maximal Lyapunov characteristic exponent (mLCE)—the average rate of divergence of nearby trajectories, which is a quantitative measure of the degree of nonintegrability and deterministic chaos [26]. We numerically solve the tangent dynamics of a small amplitude perturbation \( \chi_m(t) \) to a given (numerically obtained) trajectory \( \{\psi_m(t)\} \) [26] by integrating

\[
i\dot{\tau}^m = -\dot{\chi}_m + \chi_{m-1} + g(2|\psi_m|^2\chi_m + \psi_m^\dagger\psi_m^m). \tag{5}
\]

The mLCE follows as

\[
\Lambda(t) = \lim_{t \to \infty} (1/t) \ln (|\chi(t)|^2 / |\chi(0)|), \quad |\chi(t)| = \sqrt{\sum_{m=1}^N |\chi_m(t)|^2} \quad \text{see, e.g., Ref. [27].}
\]

Details of the integration scheme are given in the Supplemental Material [28]. In practice, we need finite but large enough averaging times on which the \( \Lambda(t) \) saturates [28].

In Fig. 2(a) we show \( P_\pm(\tau) \) for a density pair \( x = 2, y = 4 \) on the \( \beta = 0 \) line \( y_{\text{gd}}(x) \). We observe that \( P_+(\tau) \) (upper red curve) has a clear algebraic tail, while \( P_-(\tau) \) (lower blue curve) decays much faster, and in a more complex manner. In the following we will present results for the exponent \( \alpha \) for \( P_+(\tau) \) only, which reads \( \alpha = 3.2 \pm 0.1 \). By our definition, the dynamics is ergodic, despite being on the border line to the non-Gibbs phase. We plot in the inset of Fig. 2(a) the function \( P_+(\tau) \) obtained for different volumes \( N = 512, 1024, 2048, 4096 \) and conclude that we can exclude the impact of finite size effects. In Fig. 2(b), we show the time evolution of the norm density of one of the excursions which contribute to the algebraic tail [marked with the green square in Fig. 2(a)]. We observe the generation of a long lasting discrete breather like excitation out of ergodic fluctuations, which persists for a large time \( 10^3 \) and finally decays again into the thermalized surrounding. We positively tested this conclusion for many other tail excursions.

In Fig. 3 we present results for the exponent \( \alpha \) along the two characteristic lines \( y_h(x) \) and \( y_{\text{gd}}(x) \). The function \( a_h(x) \) along the \( \beta = 0 \) line \( y_{\text{gd}}(x) = x^2 \) (which separates Gibbs and non-Gibbs phases) monotonically decreases with increasing \( x \). Its value is clearly \( \alpha > 2 \) in the whole assessed range \( 0 < x < 6 \). We may anticipate that weak nonergodicity \((\alpha = 2)\) happens around \( x \sim 20-30 \) in that line. The function \( a_h(x) \) along the limiting line for homogeneous states \( y_h(x) = 2x + x^2/2 \) is monotonically decreasing with decreasing \( x \). While increasing density \( x \) enhances ergodicity on that line, we observe a transition to weak nonergodicity \( \alpha_h < 2 \) for \( x < 2 \). Let us remind that in the weakly nonergodic regime every observable becomes trajectory dependent for any finite averaging time. This dependence translates into large uncertainties in their measurement, which herewith results in the large error bars in Fig. 3 for \( \alpha \sim 2 \) (details of the estimate of the
The microcanonical thermodynamical description as well as the existence of negative temperature for weakly nonergodic dynamics is triggered by local fluctuations (discrete breatherlike excitations) which leave a part of the system well thermalized in between them. The Lyapunov exponent is sensitive to the chaotic dynamics in these thermalized puddles, but is not sensitive to the presence of weakly nonergodic boundaries between the puddles.

Let us discuss our observations. The Gross-Pitaevskii lattice dynamics is one of the remarkable cases where the large density limit yields an integrable system of disconnected anharmonic oscillators. The network of nonintegrable perturbations that couple the actions off that limit is given by the hopping part of the GP model, and is short ranged. As a consequence, the microcanonical dynamics becomes weakly nonergodic at large but finite densities for a macroscopic system, which is still at a finite distance from some integrable limit. We quantify these observations by computing distributions of excursion times off equilibrium Poincare manifolds, and measuring the exponents in their tails. Long excursion times are related to the generation of hot spots, or discrete breatherlike excitations. Our method is therefore able to quantitatively assess discrete breather lifetimes at equilibrium. Note that weakly nonergodic dynamics is going well along with nonzero Lyapunov exponents. This happens because a part of the system condenses into discrete breatherlike regions, or spots of regular dynamics, while regions between these spots still evolve in a chaotic fashion.

It is tempting to relate these observations to the existence of a non-Gibbs phase in the microcanonical GP lattice dynamics. Note that this non-Gibbs phase existence follows from the existence of a second conserved quantity (the norm also known as particle number) and is a result of a purely statistical analysis. We find that a part of the non-Gibbs phase is ergodic. Therefore, we conclude that a yet unknown new grand canonical distribution function might exist that describes the equilibrium and ergodic dynamics there, which could differ only infinitesimally from the Gibbs one close to the transition to weak nonergodicity happens well inside the non-Gibbs phase, albeit close to its boundary.

The Lyapunov exponent function $\Lambda_{\text{NE}}(x)$ along the $\beta = 0$ line $y_{\text{NE}}(x)$, and the function $\Lambda_{h}(x)$ along the $y_{h}(x)$ line, are plotted in Fig. 3 and show no anomalies, neither in the ergodic, nor in the weakly nonergodic, neither in the Gibbs, nor in the non-Gibbs phases. Therefore, we conclude that weakly nonergodic dynamics is triggered by local fluctuations (discrete breatherlike excitations) which leave a part of the system well thermalized in between them. The Lyapunov exponent is sensitive to the chaotic dynamics in these thermalized puddles, but is not sensitive to the presence of weakly nonergodic boundaries between the puddles.

Let us discuss our observations. The Gross-Pitaevskii lattice model is one of the remarkable cases where the large density limit yields an integrable system of disconnected anharmonic oscillators. The network of nonintegrable perturbations that couple the actions off that limit is given by the hopping part of the GP model, and is short ranged. As a consequence, the microcanonical dynamics becomes weakly nonergodic at large but finite densities for a macroscopic system, which is still at a finite distance from some integrable limit. We quantify these observations by computing distributions of excursion times off equilibrium Poincare manifolds, and measuring the exponents in their tails. Long excursion times are related to the generation of hot spots, or discrete breatherlike excitations. Our method is therefore able to quantitatively assess discrete breather lifetimes at equilibrium. Note that weakly nonergodic dynamics is going well along with nonzero Lyapunov exponents. This happens because a part of the system condenses into discrete breatherlike regions, or spots of regular dynamics, while regions between these spots still evolve in a chaotic fashion.

It is tempting to relate these observations to the existence of a non-Gibbs phase in the microcanonical GP lattice dynamics. Note that this non-Gibbs phase existence follows from the existence of a second conserved quantity (the norm also known as particle number) and is a result of a purely statistical analysis. We find that a part of the non-Gibbs phase is ergodic. Therefore, we conclude that a yet unknown new grand canonical distribution function might exist that describes the equilibrium and ergodic dynamics there, which could differ only infinitesimally from the Gibbs one close to the transition to weak nonergodicity happens well inside the non-Gibbs phase, albeit close to its boundary.

The Lyapunov exponent function $\Lambda_{\text{NE}}(x)$ along the $\beta = 0$ line $y_{\text{NE}}(x)$, and the function $\Lambda_{h}(x)$ along the $y_{h}(x)$ line, are plotted in Fig. 3 and show no anomalies, neither in the ergodic, nor in the weakly nonergodic, neither in the Gibbs, nor in the non-Gibbs phases. Therefore, we conclude that weakly nonergodic dynamics is triggered by local fluctuations (discrete breatherlike excitations) which leave a part of the system well thermalized in between them. The Lyapunov exponent is sensitive to the chaotic dynamics in these thermalized puddles, but is not sensitive to the presence of weakly nonergodic boundaries between the puddles.

Let us discuss our observations. The Gross-Pitaevskii lattice model is one of the remarkable cases where the large density limit yields an integrable system of disconnected anharmonic oscillators. The network of nonintegrable perturbations that couple the actions off that limit is given by the hopping part of the GP model, and is short ranged. As a consequence, the microcanonical dynamics becomes weakly nonergodic at large but finite densities for a macroscopic system, which is still at a finite distance from some integrable limit. We quantify these observations by computing distributions of excursion times off equilibrium Poincare manifolds, and measuring the exponents in their tails. Long excursion times are related to the generation of hot spots, or discrete breatherlike excitations. Our method is therefore able to quantitatively assess discrete breather lifetimes at equilibrium. Note that weakly nonergodic dynamics is going well along with nonzero Lyapunov exponents. This happens because a part of the system condenses into discrete breatherlike regions, or spots of regular dynamics, while regions between these spots still evolve in a chaotic fashion.
Hamiltonian systems with bounded spectrum have been questioned by Dunkel et al. in Ref. [32]. Their argument says that, in order to describe the thermodynamics of such systems, the Gibbs entropy has to be employed, which implies the nonexistence of negative temperature. In our case, we followed the microcanonical ergodic dynamics defined with the Boltzmann temperature and is proven to be valid in the defined Gibbs phase. Moreover, it has been recently shown that the Boltzmann entropy (which admits negative temperatures) provides the correct description of the microcanonical thermodynamics of systems like the GP [33,34] (further discussions can be found in Refs. [4–8]).

To conclude, we applied a novel method of statistical analysis of excursion times off equilibrium Poincare manifolds to the transition from ergodic to nonergodic dynamics in the Gross-Pitaevskii lattice model. Our results are in analogy with the weak nonergodicity phenomena studied in glass systems [14], continuous-time random walks [15–17], as well as in other many-body systems [19]. We expect them to be applicable also to larger spatial dimensions, and to other lattice models with similar integrable limits. We also speculate that spatial disorder, which induces Anderson localization, at small densities, are in analogy with the weak nonergodicity phenomena in the Gross-Pitaevskii lattice model. Our results say that, in order to describe the thermodynamics of such systems, the Gibbs entropy has to be employed, which implies the nonexistence of negative temperature. In our case, we followed the microcanonical ergodic dynamics defined with the Boltzmann temperature and is proven to be valid in the defined Gibbs phase. Moreover, it has been recently shown that the Boltzmann entropy (which admits negative temperatures) provides the correct description of the microcanonical thermodynamics of systems like the GP [33,34] (further discussions can be found in Refs. [4–8]).
